SUMMARY

Bone marrow transplantation is the primary therapy for numerous hematopoietic disorders. The efficiency of bone marrow transplantation depends on the function of long-term hematopoietic stem cells (LT-HSCs), which is markedly influenced by their hypoxic niche. Survival in this low-oxygen microenvironment requires significant metabolic adaptation. Here, we show that LT-HSCs utilize glycolysis instead of mitochondrial oxidative phosphorylation to meet their energy demands. We used flow cytometry to identify a unique low mitochondrial activity/glycolysis-dependent subpopulation that houses the majority of hematopoietic progenitors and LT-HSCs. Finally, we demonstrate that Meis1 and Hif-1α are markedly enriched in LT-HSCs and that Meis1 regulates HSC metabolism through transcriptional activation of Hif-1α. These findings reveal an important transcriptional network that regulates HSC metabolism.

INTRODUCTION

The microenvironment, or niche, plays a crucial role in self-renewal and differentiation of hematopoietic stem cells (HSCs) (Fuchs et al., 2004; Spradling et al., 2001). One of the hallmarks of the HSC niche is its low-oxygen tension, hence the term “hypoxic niche” (Chow et al., 2001a; Parmar et al., 2007). This low-oxygen environment is not only tolerated by HSCs, but also appears to be essential for their function (Bradley et al., 1978; Chow et al., 2001a; Cipolleschi et al., 1993; Danet et al., 2003; Eliasson and Jönsson, 2010; Katahira and Mizoguchi, 1987; Koller et al., 1992; Kubota et al., 2008; Laluppa et al., 1998; Lo Celso et al., 2009; Parmar et al., 2007). The mechanism of this hypoxic tolerance of HSCs, while poorly understood, requires significant metabolic adaptation.

Hif-1 is a master regulator of metabolism. It regulates both glycolysis and mitochondrial respiration, inducing a metabolic shift toward anaerobic glycolysis (Hägg and Wennström, 2005; Kim et al., 2006b; Marin-Hernández et al., 2009; Maxwell et al., 2007; Papandreou et al., 2006; Wang et al., 1995; Zhang et al., 2007). Hif-1 function is dependent on dimerization of the constitutively active Hif-1β subunit and the tightly regulated Hif-1α subunit. Hif-1α undergoes hydroxylation, followed by ubiquitination and degradation during normoxia in most cells (Ivan et al., 2001; Jaakkola et al., 2001; Kamura et al., 2000; Maxwell et al., 1999; Salceda and Caro, 1997). Upregulation of Hif-1α can occur either by transcriptional activation (Hirota et al., 2004; Laughner et al., 2001) or protein stabilization (Li et al., 2005; Nakayama et al., 2004; Qi et al., 2008; Semenza, 2007). Several studies have demonstrated that Hif-1α may play a crucial role in HSCs (Iyer et al., 1998; Ryan et al., 1998) (Kim et al., 2006a); however, the function and mechanism of regulation of Hif-1α in HSCs remain largely unknown.

Meis1 belongs to the Hox family of homeobox genes, which is an evolutionarily conserved set of genes that encode DNA-binding transcription factors (Krumlauf, 1994). Meis1 is expressed in the most primitive hematopoietic populations and is downregulated upon differentiation (Argiropoulos et al., 2007; Imamura et al., 2002; Pineault et al., 2002). Moreover, targeted Meis1 knockout causes lethality by embryonic day 14.5 with multiple hematopoietic and vascular defects (Azcoitia et al., 2005; Hisa et al., 2004; Imamura et al., 2002). Despite the clear association of Meis1 with HSCs, the precise function of Meis1 in HSCs is not well understood.

In the current study, we outline the unique metabolic characteristics of LT-HSCs and we show that separation of bone marrow cells solely based on their metabolic footprint markedly enriches for HSCs. Finally, we demonstrate that Meis1 regulates HSC metabolism through transcriptional activation of Hif-1α.

RESULTS

Metabolic Profile of Mouse LT-HSCs

Lin−, Sca-1+, c-Kit+, CD34−, and Flk2− (LT-HSCs) cells have low rates of mitochondrial respiration (Figure 1A) and low levels of
ATP (Figure 1B). Lower rates of mitochondrial respiration can be attributed to lower energy requirements (i.e., quiescence) and/or utilization of glycolysis instead of oxidative phosphorylation. Therefore, we examined the overall glycolytic flux as determined by the rate of glucose-derived $^{13}$C lactate production. As shown in Figure 1C, the rate of glucose-derived $^{13}$C lactate production...
was higher in LT-HSCs compared to whole bone marrow when normalized to cellular ATP. This method determines the source of lactate and not only the amount of lactate produced. This is important because cells can produce lactate from the metabolism of glutamine rather than glucose (DeBerardinis et al., 2007).

Next, we determined the metabolic profile of LT-HSCs by flow cytometry. Whole mouse bone marrow underwent lineage depletion, then was concomitantly stained for Sca-1+, c-Kit+, CD34−, and Flk2− surface expression and for mitotracker incorporation. Cells were also assessed for endogenous NADH fluorescence. These techniques allow profiling of cells based on their mitochondrial proton gradient in the case of mitotracker (Poot et al., 1996) and endogenous NADH fluorescence (Chance and Thorell, 1959) as an index of overall mitochondrial respiration (as the majority of cellular NADH is derived from mitochondrial respiration). The majority of LT-HSCs were localized to a well-defined flow cytometry gate, which contained 6%–9% of total bone marrow cells. Cells in this gate were characterized by low mitochondrial potential (MP) (Figures 1D and 1E) and low NADH fluorescence (Figure 2A). This low MP population contained >80% of LT-HSCs (Figure 1F). Lineage characterization of the low MP population demonstrated that LT-HSCs and...
Lineage^−, Sca-1^−, c-Kit^+ (LSK) cells are the only two populations that are largely localized to the low MP gate, whereas all other lineages had mostly high mitochondrial potential (Figure 1F). Moreover, this low MP gate, although markedly enriched in LT-HSCs and LSK cells, contains all other bone marrow lineages (Figure 1G). To exclude the possibility that this low mitotracker profile is secondary to dye efflux, we used Fumitremorgin C (FTC), a specific blocker of the ABCG2 transporter. The ABCG2 transporter is responsible for dye efflux by the side population (SP) stem cells (Goodell et al., 1997; Scharenberg et al., 2002; Zhou et al., 2001). As shown in Figure 1H, FTC had no effect on the percentage of cells in the low MP gate.

Metabolic Characteristics of High and Low MP Cells
We next characterized the metabolic properties of cells in the low MP gate as they compare to cells with high MP. First, we directly correlated endogenous NADH fluorescence with mitotracker fluorescence. NADH fluorescence is an index of mitochondrial oxidative phosphorylation given that oxidative metabolism yields a significantly higher amount of NADH for each molecule of glucose oxidized when compared to glycolysis (eight molecules NADH compared to two molecules, respectively) (Chance and Thorell, 1959). As shown in Figure 2A, high and low mitotracker cells displayed high and low NADH fluorescence cells, respectively. This result is supported by measurement of oxygen consumption, where the high MP cells displayed significantly higher oxygen consumption rates compared to the low MP cells (Figure 2B).

Low MP cells also preferentially utilized glycolysis for their metabolic needs. As shown in Figure 2D, the rate of ^13^C lactate production was significantly higher in the low MP cells. We further confirmed this finding by using a specific mitochondrial electron transport chain inhibitor. Inhibition of the electron transport chain complex III by antimycin A (AMA) results in NADH accumulation only in cells that rely on mitochondrial respiration for NADH production. We used this principle to evaluate the source of NADH in high and low MP cells. As shown in Figure 2E, only a small percentage of the low MP cells displayed increased NADH after AMA treatment compared to high MP cells, indicating that mitochondrial respiration is not the main source of NADH in low MP cells. Taken together, these results indicate that the low MP cells do not rely on mitochondrial respiration for energy production, but rather on cytoplasmic glycolysis.

Low MP Cells Are Primed for Hypoxia Resistance
We performed a PCR array for hypoxia related gene expression on freshly isolated high and low MP cells. Under normoxic conditions, the low MP cells displayed significant upregulation of numerous hypoxia-inducible genes and regulatory glycolysis genes (Figure 3A) compared to high MP cells. This was further confirmed by upregulation and stabilization of Hif-1α protein (RNA in Figure 3A and Figure S2A available online, and protein in Figures 3B and 3C) in the low MP cells. These results not only provide a mechanistic explanation of the metabolic phenotype of low MP cells but also suggest that the low MP cells are primed for adaptation to low-oxygen environment. This was corroborated by the significantly higher viability of low MP cells following both severe hypoxic and anoxic stresses (Figure 3D).

Collectively, these results indicate that cells in the low MP gate utilize glycolysis instead of mitochondrial respiration for their energy demands. This metabolic phenotype is associated with normoxic upregulation of Hif-1α and its downstream target genes.

Stem Cell Characteristics of Metabolically Sorted Cells
Given the unique metabolic characteristics of LT-HSCs, we tested whether isolation of bone marrow cells solely based on their metabolism enriches for HSC. After flow cytometric separation of high and low MP cells, we evaluated their gene expression profile with PCR array. Figure 4A demonstrates that low MP cells express higher levels of numerous HSC-associated transcripts.

Furthermore, we utilized in vitro and in vivo hematopoietic progenitor and HSC assays to characterize the stem cell properties of low MP cells. Low and high MP cells were cultured in methocult medium and the colonies were evaluated after 12 days. Low MP cells displayed a much higher colony forming capacity compared to high MP cells (Figure 4B). Further characterization of colony types revealed that the low MP cell produced a higher percentage of CFU-GEMM type (mixed colonies) with lower percentages of BFU-E and CFU-GM colonies compared to high MP cells (Figures 4C–4E), although the low MP population had significantly higher number of all types of colonies. These results indicate that low MP cells are enriched for hematopoietic progenitor cells.

In vivo bone marrow reconstitution studies following lethal irradiation were undertaken to determine the long-term reconstitution capacity of low MP cells. Serial analysis of the peripheral blood of the recipient mice demonstrated a significantly higher percentage of engraftment with the low MP cells compared to high MP cells at all time points (Figures 4F and 4G). Moreover, peripheral blood cells were collected and analyzed by flow cytometry with lineage markers to determine the capacity of low MP cells to repopulate different hematopoietic lineages. As shown in Figure S1A, the low MP cells repopulated all tested lymphoid (CD45.2^+Thy1.2^+, CD45.2^+B220^+) and myeloid lineages (CD45.2^+Mac-1^+, CD45.2^+Gr-1^+). Additional studies were undertaken in which the bone marrow was depleted of HSCs by flow cytometric separation of LSK cells, followed by equal distribution of LSK cells to the high and low MP populations. Bone marrow reconstitution studies using these high and low MP populations with equal numbers of HSCs demonstrated no difference in transplantation efficiency (Figure S1B). This confirms that the enhanced reconstitution capacity by the low MP population is due to localization of LT-HSCs to the low MP gate. Collectively, these results confirm that the low MP cell fraction of the bone marrow is highly enriched in both hematopoietic progenitors and long-term repopulating HSCs.

Expression of Hif-1α in LT-HSCs
In order to determine the mechanism of the glycolytic metabolic phenotype of LT-HSCs, we evaluated the expression pattern of Hif-1α in LT-HSCs and WBM (Figure 5A). WBM and LT-HSCs underwent fixation followed by permeabilization and immunochemical staining for Hif-1α. Here, we show that the majority (89%) of LT-HSCs express Hif-1α, whereas less than 30% of the WBM cells are Hif-1α positive. Upregulation of Hif-1α mRNA was confirmed by real-time PCR as shown in Figure S2B.
Figure 3. Normoxic Upregulation of Hif-1α in Low MP Cells

(A) Hypoxia real-time PCR array profile of low MP cells compared to high MP cells. Note the significant normoxic upregulation of hypoxia inducible genes in low MP cells under normoxic conditions (5–6 hr after isolation).

(B) Upper panel(s) show western blot analysis of high and low MP cells with Hif-1α antibody and actin as loading control. The lower panel shows densitometry analysis demonstrating higher Hif-1α protein expression in the low MP cells (n = 3).

(C) Immunocytochemistry staining demonstrating a higher percentage of low MP cells expressing Hif-1α compared to high MP cells (n = 3).
Meis1 Is a Transcriptional Activator of Hif-1α

Meis1 is a HSC-associated transcription factor required for definitive hematopoiesis; however, its precise role in HSCs is not well understood. We determined that whereas only a small percentage of WBM cells express Meis1 protein (1.4%), the vast majority of LT-HSCs are Meis1 positive (96.2%) (Figure 5B). Moreover, we colocalized Hif-1α and Meis1 proteins by immunocytochemistry and found that the majority of Meis1 positive cells were also positive for Hif-1α (85.2%) (Figure 5C). This expression pattern of Hif-1α and Meis1 remained unchanged after isolation of bone marrow cells, indicating that the expression of Hif-1α may not be simply secondary to the in vivo environment in the bone marrow.

These findings led us to examine whether Hif-1α expression by LT-HSCs is downstream of the HSC-associated transcription factor Meis1. We identified an evolutionarily conserved Meis1 consensus binding sequence in the Hif-1α first intronic region (Figure 5D). Luciferase assays were carried out with wild-type Hif-1α promoter (Hif1-α-pGL2) and a Hif-1α promoter harboring a mutated Meis1 binding sequence (mut-TGAC-Hif-1α-pGL2). Increasing concentrations of Meis1 expression vector (CMV-M-Meis1) resulted in dose-dependent transcriptional activation of Hif-1α. This activation was dependent on binding of Meis1 to its consensus binding sequence in the Hif-1α first intronic region because mutation of the seed sequence completely abolished the activation of Hif-1α by Meis1 (Figure 5E).

To determine whether Meis1 is required for Hif-1α expression, we utilized siRNA to knockdown Meis1 in freshly isolated LT-HSCs. Scrambled Meis1 siRNA was used as control. Transfection with Meis1 siRNA resulted in diminution of Meis1 mRNA levels. This was associated with a marked downregulation of Hif-1α mRNA (Figure 5F). Taken together, these results indicate that Meis1 is required for optimal transcriptional activation of Hif-1α in LT-HSCs.

To confirm the in vivo binding of Meis1 to its conserved sequence in the Hif-1α gene, we performed chromatin immunoprecipitation (ChIP) assays in Kasumi1 cells. The results confirmed that Meis1 binds in vivo to its conserved sequence in the Hif-1α first intronic region as determined by real-time PCR following immunoprecipitation with Meis1 antibody (Figure 5H). PCR products are shown in the right panel.

Discussion

Stem cell separation techniques generally rely on the pattern of expression of specific membrane proteins. As a result, isolation of HSCs requires the combination of several antibodies such that stem cells are defined by the presence or absence of certain epitopes or markers (Challen et al., 2009; Goodell et al., 1996; Kiel et al., 2007; McCune et al., 1988; Murray et al., 1995; Péault et al., 1993). Although several reports have indicated that HSCs are resistant to hypoxia (Cipolleschi et al., 1993) and reside within hypoxic niches in the bone marrow (Chow et al., 2001b; Li and Li, 2006; Parmar et al., 2007), these characteristics have not been exploited for identification of unique metabolic properties of HSCs, or for HSC enrichment.

In the current study, we define the metabolic phenotype of mouse HSCs. We demonstrate that LT-HSCs cells are localized to a distinct population of cells characterized by low mitochondrial potential (low MP). This population represents only 6%–9% of the total bone marrow, but contains >80% of LT-HSCs, determined by surface marker expression. We show that both LT-HSCs and low MP cells have low ATP levels and utilize cytoplasmic glycolysis instead of mitochondrial oxidative phosphorylation. This metabolic phenotype is associated with upregulation of Hif-1α, at both the transcript and the protein levels. Separation of cells solely based on this metabolic profile markedly enriches for HSCs as determined by in vitro colony forming assays and in vivo long-term repopulation assays. Finally, we show that the HSC-associated transcription factor Meis1 regulates HSC metabolism through transcriptional activation of Hif-1α.

Hif-1α is a master regulator of metabolism known to regulate various aspects of cellular response to hypoxic stress. Although the mechanism of oxygen-dependent posttranslational regulation of Hif-1α is well understood, little is known about its transcriptional regulation. A number of reports indicate that Hif-1α is regulated at the transcriptional level both during hypoxia and normoxia (Belaiba et al., 2007; Blouin et al., 2004; Hirota et al., 2004; Jiang et al., 1997; Laughner et al., 2001; Liu et al., 2004). In the current study, we show that Meis1 activates Hif-1α transcription in LT-HSCs through binding to its conserved consensus binding sequence in the Hif-1α first intronic region.

The metabolic phenotype of HSCs outlined here is supportive of the adaptability of HSCs to the physiologic low-oxygen tension in the bone marrow hypoxic niches. Under these hypoxic conditions, glycolytic metabolism predominates and can provide sufficient amounts of ATP to sustain HSCs. This metabolic phenotype also confers a survival advantage on HSCs during severe hypoxic or anoxic insults that would invariably eliminate differentiated cells that rely on oxidative metabolism. Importantly, the transcriptional regulation of Hif-1α by Meis1 highlights the involvement of stem cell-associated transcription factors in regulation of HSC metabolism and indicates that the glycolytic phenotype of HSCs is not merely a product of their hypoxic environment.

Experimental Procedures

LT-HSC Isolation

LT-HSCs were isolated from the bone marrow cells of 4- to 6-month-old C57BL/6 mice by FACS after surface marker staining for Lin, Sca-1, C-Kit, CD34, and Flk2 to identify Lin−, Sca-1+ C-Kit+, and CD34/Flk2− cells (LT-HSCs). All antibodies were purchased from BD PharMingen. In studies where LT-HSCs were isolated for metabolic analysis, magnetic lineage depletion (autoMACS separator, Miltenyi Biotec) was utilized. In these studies, additional
control fluorescent surface marker staining was performed, and the cells were evaluated by flow cytometry for ensuring that adequate lineage depletion (>95% lineage depletion) was reproducibly achieved. For metabolic studies, LT-HSCs isolated from 62 mice were pooled, and metabolic studies were performed within 24 hr of isolation.

**Metabolic Assays**

Oxygen consumption was measured with the BD Oxygen Biosensor System in accordance with the manufacturer’s recommendations. A total of 2 to 3 x 10^5 cells/well were used. Oxygen consumption was determined after 2 hr of culture in the biosensor.

ATP levels were quantified with ATP Bioluminescence Assay Kit HS II (Roche) in accordance with the manufacturer’s recommendations. A total of 2 to 3 x 10^5 cells/well were used.

Lactate production was measured with gas chromatography-mass spectrometry. Cells were cultured for 12 hr in a medium supplemented with 10 mM D-[1-13C]-glucose (Cambridge Isotope Labs) to allow up to half of the glucose-derived lactate pool to be labeled on C-3. The samples were analyzed for lactate abundance. The final results are presented as nMoles 13C-Lactate/nMol ATP.

Mitochondrial source of NADH was determined with the electron transport chain complex III inhibitor antimycin A (AMA). AMA leads to cessation of electron transport.

---

**Figure 4. Low MP Cells Are Enriched for HSCs**

(A) PCR array profile of low MP cells compared to high MP cells demonstrating enrichment of a number of HSCs associated genes in the low MP population. (B) The left panel shows a representative bright field microscopic image of colonies obtained from low and high MP cells. The right panel shows quantification of colonies derived from low and high MP cells in methocult after 12 days. (C) GFU-GEMM colonies. (D) CFU-GM colonies. (E) BFU-E colonies (n = 3). Note the significantly higher number of colonies derived from the low MP population. These results indicate that the low MP population is markedly enriched for hematopoietic progenitor cells. (F) Representative flow cytometry profiles of peripheral blood of bone marrow recipient mice after staining with anti-CD45.2-FITC antibody (x axis) and anti-CD45.1-PE antibody (y axis), demonstrating higher engraftment in the recipient of low MP cells. (G) Time course analysis of bone marrow reconstitution with low and high MP cells (n = 5 animals/group). Note the significantly higher bone marrow repopulation capacity of the low MP cells at all time points. This result indicates that the low MP population is enriched for long term repopulating HSCs. Data presented as mean ± SEM. See also Figure S1.
flow through the respiratory chain resulting in rapid accumulation of NADH from the Krebs cycle. Stock AMA (Sigma Aldrich) was prepared at 1 M in DMSO. A baseline NADH fluorescence gate was set with untreated high and low MP cells. High and low mitochondrial potential cells were then treated with 2 µM AMA for 5 min and profiled for NADH fluorescence. Cells with mitochondrial source of NADH production display an increase in NADH fluorescence following AMA treatment.

Figure 5. Transcriptional Regulation of Hif-1α by Meis1

(A) Expression pattern of Hif-1α. The left panel shows expression of Hif-1α in WBC. The middle panel shows expression of Hif-1α in LT-HSCs. The right panel shows quantification of Hif-1α expression. Note that whereas less than 25% of the unfractionated bone marrow cells express Hif-1α, the vast majority of LT-HSCs express Hif-1α protein (n = 3).

(B) Expression pattern of Meis1. The left panel shows expression of Meis1 in WBM. The middle panel shows expression of Meis1 in LT-HSCs. The right panel shows quantification of Meis1 expression. Note that whereas less than 2% of the unfractionated bone marrow cells express Meis1, almost all the LT-HSCs express Meis1 protein (n = 3).

(C) Colocalization of Hif-1α and Meis1 in the WBM. The left panel shows a representative flow cytometry profile of the expression of Hif-1α and Meis1. The right panel shows quantification of Hif-1α and Meis1 expression. Note that although only a small percentage of WBM cells express Meis1, the majority of these Meis1+ cells also coexpress Hif-1α (n = 3).

(D) Schematic of the conserved Meis1 binding domain in the first intronic region Hif1-α.

(E) Luciferase assay demonstrating dose dependent increase in Hif-1α luciferase activity after transfection with Meis1 expression vector. Mutation of the four nucleotides Meis1 seed region completely abolishes the luciferase activity (n = 3).

(F) Real-time PCR following siRNA knockdown of Meis1 in freshly isolated LT-HSCs. Knockdown of Meis1 in LT-HSCs (5.6-fold) resulted in marked downregulation of Hif-1α mRNA levels (4.5-fold), (n = 3).

(G) ChIP assay demonstrating in vivo binding of Meis1 to its consensus binding sequence in the Hif1-α first intron. The left panel shows real-time PCR with primers flanking the consensus Meis1 binding sequence compared to control IgG after immunoprecipitation. The right panel shows PCR products showing input control and negative ampiclon (n = 3). Data presented as mean ± SEM.

Flow Cytometric Profiling and Separation of Cells Based on Mitochondrial Activity

Flow cytometric profiling and separation of BM cells based on their mitochondrial activity was performed with mitotracker dyes and endogenous NADH fluorescence. The metabolic profile of mouse LT-HSCs was determined with concomitant surface marker and mitotracker staining. Mitotracker dyes that accumulate within mitochondria on the basis of mitochondrial proton gradient (MitoTracker deep red 633, MitoTracker Red CMXROS and MitoTracker Red CM-H2XRos) (Poot et al., 1996), as well as nonproton gradient sensitive dyes (MitoTracker Green), were used. Endogenous NADH fluorescence was measured flow cytometrically at 37°C with a UV laser (Ex: 350 nm, Em: 460 nm, Mollo analyzer, Cytomation) as described previously (Chance and Thorell, 1959). Flow cytometric separation of high and low MP cells was carried out by separating cells in the low MP gate (6%–9%) and an equivalent number of cells with high mitochondrial potential.

Stem Cell Assays

Colony forming cell (CFC) assays were performed on high and low MP cells separated solely on the basis of the flow cytometric mitochondrial profile according to recommendations (Methocult, Stem Cell Technologies). For in vivo bone marrow reconstitution studies, high and low MP cells were isolated from 8- to 10-week-old C57BL/6 CD45.2 mice. Equal numbers of high and low MP CD45.2 donor cells (5 x 10^5) were mixed with 5 x 10^4 freshly isolated CD45.1 competitor bone marrow cells, and the mixture was injected intravenously via the retro-orbital route into each of a group of 6- to 9-week-old CD45.1 mice previously irradiated with a total dose of 10 Gy. For measuring reconstitution of transplanted mice, peripheral blood was collected at the indicated times after transplant and the presence of CD45.1+ and CD45.2+ cells in lymphoid and myeloid compartments were measured as described (Zhang and Lodish, 2004, 2005). Separate studies were performed were LSK cells were depleted from the bone marrow by flow cytometry, followed by equal distribution of LSK cells to high and low MP populations (1500 LSK cells per group). CD45.2 high and low MP donor cells (5 x 10^5) were mixed with 5 x 10^4 freshly isolated CD45.1 competitor bone marrow cells.

Gene Profile of Low and High MP Cells

RNA was extracted from high and low MP cells by using TRIzol (Invitrogen) in accordance with the manufacturer’s instructions. cDNA was retrotranscribed with an RT-PCR kit (SA Biosciences). Mouse Real-Time Syber Green PCR Mix was purchased from SuperArray. PCR was performed on an ABI Prism 7700 Sequence Detector (Applied Biosystems). HSCs and hypoxia primer sets (SABiosciences) were used. The data were analyzed with the DDCT method.

Intracellular Detection of Hif-1α and Meis1 Proteins

Hif-1α by Meis1 proteins were detected by immunocytochemistry as follows; fresh bone marrow cells underwent fixation with 4% paraformaldehyde for 10 min at room temperature. After permeabilization (0.01% Triton) and serum block, cells were incubated overnight with primary antibodies (1:50 dilution anti-Hif-1α and 1:50 dilution anti-Meis1). Staining was assessed by flow cytometry after incubation with corresponding fluorophore-conjugated secondary antibody.

Transcriptional Activation of Hif-1α by Meis1

Luciferase reporter assay was performed with an 818 bp long DNA fragment from the first intronic region of Hif-1α containing the conserved Meis1 binding site (+1799 bp from ATG start site, chr14:61,232,973-61,233,790) was amplified from mouse genomic DNA and used for generation of TGAC-Hif-1α-pGL2 and mut-TGAC-Hif-1α-pGL2 reporter vectors. Transcriptional activation of Hif-1α by Meis1 was evaluated with Hif-1α-pGL2 and mut-TGAC-Hif-1α-pGL2 vectors. Meis1 siRNA knockdown was carried out in freshly isolated LT-HSCs (4 x 10^5 cells/reaction). Cells were transfected with 50 nM of Silencer Select Custom-designed siRNA corresponding to Meis1 (hsa37712), and non-targeting control siRNA (Silencer Select Negative Control #1 siRNA, Applied Biosystems). Transfections were performed with the Amaxa Nucleofector device (program Y-001) with Amaxa CD34+ Cell Nucleofector Kit (Lonza Cologne AG) in accordance with the manufacturer’s instructions. After incubation at 37°C for 20 hr, transfected LT-HSCs cells were harvested and analyzed by real-time PCR with Meis1 and Hif-1α primers.

ChiP assay was performed to evaluate the in vivo binding of Meis1 to its consensus sequence in the Hif-1α enhancer region. The assays were done using the ChiP kit (Upstate, cat#17-295) according to the manufacturer’s instructions. Meis1 polyclonal antibody (Santa Cruz, cat# sc-10599) was utilized.

Statistical Analysis

Significance levels were calculated with a Student’s t test.
